LIST OF TABLES

1. Instruments used at the LLNL tower.
2. Percent of data recovered for LLNL tower data set (1979-1987).
3. Lateral Wind direction Turbulence criteria for initial estimate of Pasquill stability category (Brode, 1987).
4. Wind speed adjustment for determining final estimate of Pasquill Stability Category from σ_θ .
5. Joint frequency of occurrence of 10-m wind speed and P-G stability class at LLNL presented as percent of 9 years of hourly averages (1979 to 1987).
6. Mixing height (m) at Livermore, CA, estimated from Holtzworth (1972).
7. Mixing height (m) for each P-G stability category at Livermore, CA.
8. Maximum and minimum mean temperatures for LLNL tower data set (1979 to 1987).
9. Mean maximum and minimum relative humidity for LLNL tower data set (1979 to 1987).
10. Absolute humidity as a function of temperature and relative humidity.
11. Absolute humidity statistics for LLNL tower data set (1979-1987).
12. Joint frequency distribution of the wind speeds at B-222 and the LLNL tower (10 m) for February and March 1988 given in percent.
13. Joint frequency distribution of the wind speeds at B-222 and the LLNL tower (40 m) for February and March 1988 given in percent.

CLIMATOLOGY OF LAWRENCE LIVERMORE

NATIONAL LABORATORY

ABSTRACT

Meteorological data collected from 1979 to 1987 at Lawrence Livermore National Laboratory are analyzed in this report. These data are 15-min averages of wind speed, wind direction, standard deviation of the wind direction, temperature, and relative humidity. Calculated values include crosswind turbulence, absolute humidity, and stability class. Hourly averages were computed and used for most of the analysis. Frequency distributions of wind speed and horizontal wind fluctuations as well as joint frequency distributions of wind speed, wind direction, and stability are presented. The data show a marked seasonal variability and this phenomenon is explored in depth. An example is presented to show how the data set may be queried to find the probability of a specific set of meteorological conditions. In addition, a comparison is made of these data and data from another tower located nearby. The data are very similar despite slight differences, which may be explained by differences between the sampling locations in surface roughness and proximity to buildings.

INTRODUCTION

Meteorological data have been collected at the Lawrence Livermore National Laboratory (LLNL) since January 1979. Data were collected from a 40-m tower maintained by the Plant Engineering Department (1979 to 1984) and by the Environmental Protection Department (1985 to present). The tower's location was near the northeast corner of the laboratory (Figure 1). Meteorological data can be used to establish a climatology for LLNL, which is useful for planning and modeling purposes. Data were also collected from a weather station located on the exhaust stack of Building 222 during February and March 1988; these data were compared to the data from the LLNL tower to verify the applicability of the climatology established from the LLNL tower data to other portions of the laboratory.

TOPOGRAPHIC AND LARGE-SCALE INFLUENCES

Figure 2 shows the local topography that influences wind flow in Livermore, California. Because LLNL is in a region of coastal influence, prevailing winds would be expected to come from the west (the direction of the Pacific Ocean). However, LLNL lies in the southeastern portion of a bowl-shaped valley. As air enters the basin from the Dublin Gap to the west of LLNL, it diverges north and south until it encounters an obstruction to its flow. To the north, it encounters Mt. Diablo and the Altamont Hills, which turn the flow toward the southeast. To the south of the Dublin Gap, it

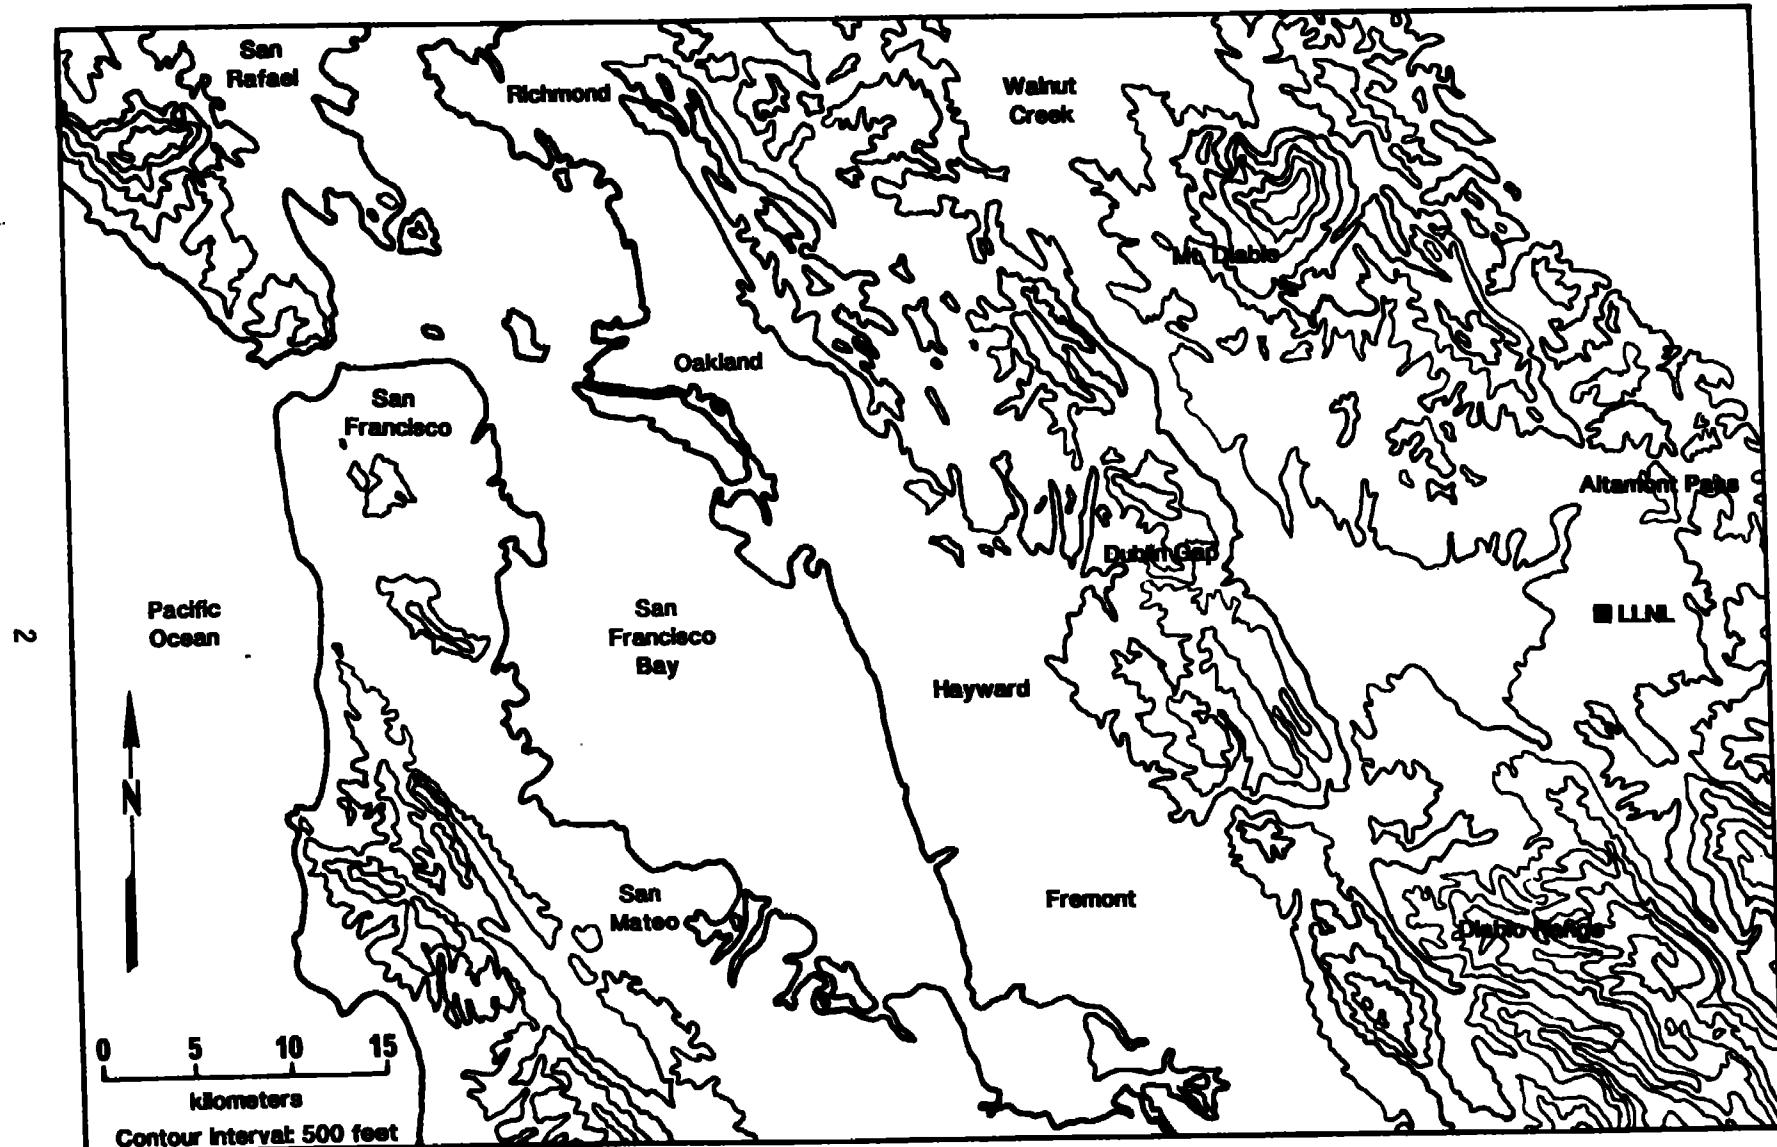

Figure 1. Topography of the San Francisco Bay Area.

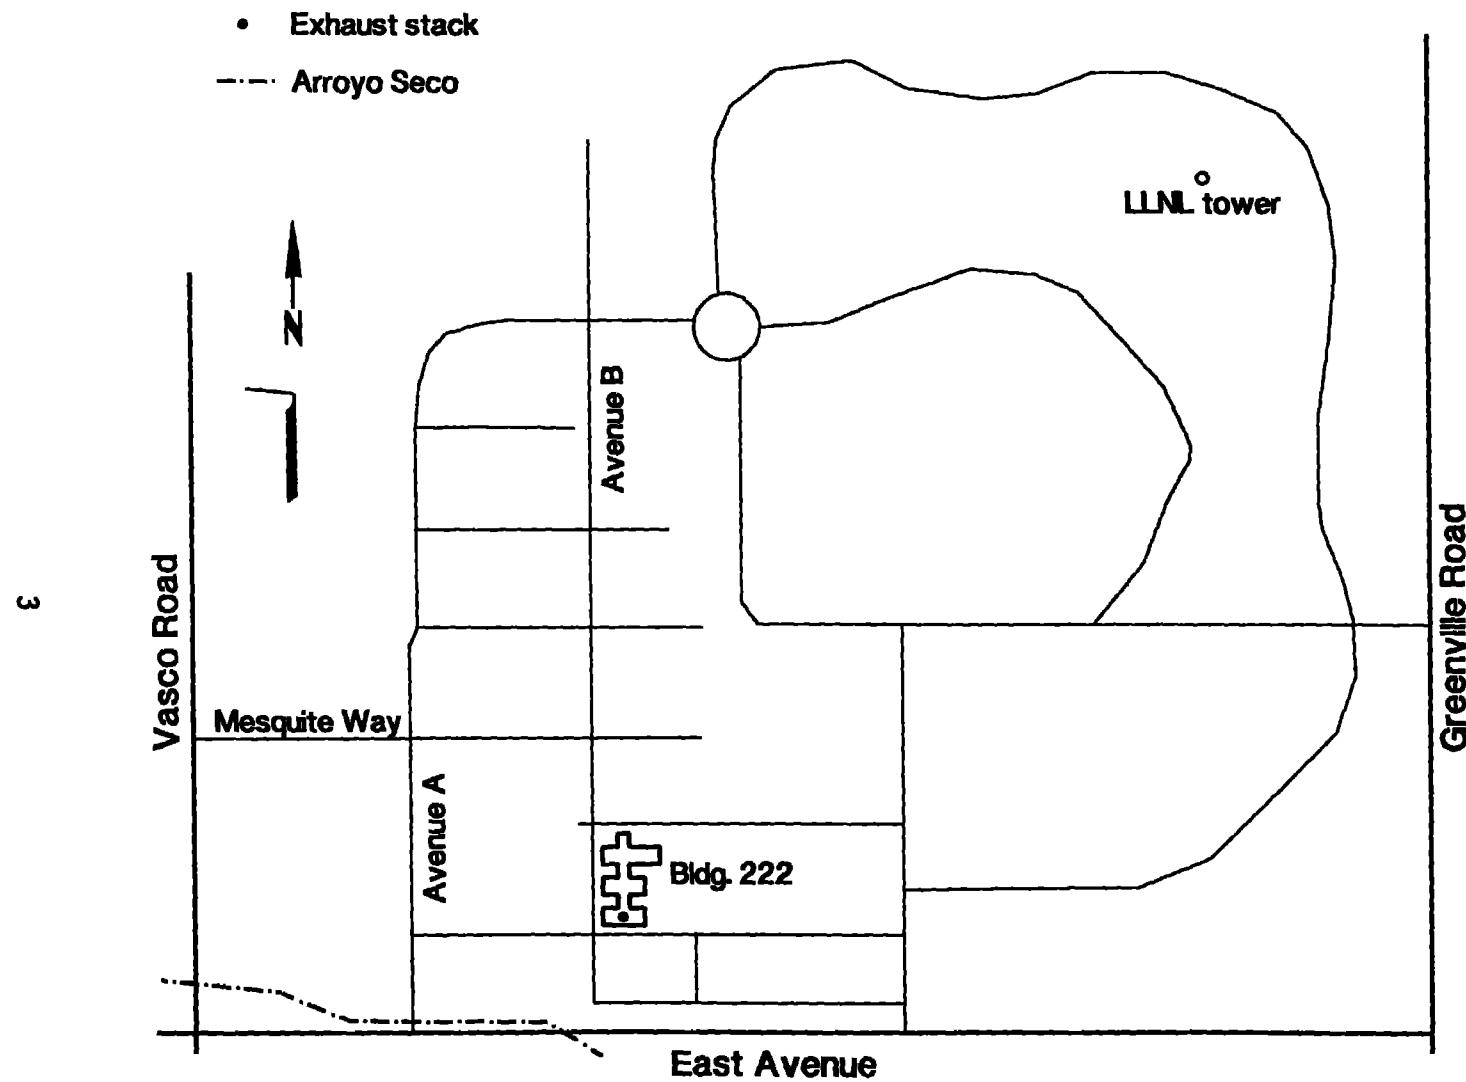

Figure 2. Lawrence Livermore National Laboratory.

encounters the foothills of the Diablo Range and the Altamont Hills, which turn the flow southwesterly (toward the northeast). The flow then exits the Livermore Valley through Altamont Pass just to the northeast of LLNL. This surface-flow pattern can be enhanced or weakened by large-scale upper-air influences.

During the summer months, afternoon wind speeds are generally higher than morning and night wind speeds due to differential surface heating. Solar heating throughout the day causes air near the land surface to heat more rapidly than air over water and to rise and be replaced with air that was once over the cooler body of water, the Pacific Ocean. It is during this period of replacement that wind speeds increase. The increased speeds usually occur around 1400 to 1600 PST. This phenomenon is commonly called a sea breeze.

Sea-breeze activity is seldom seen during the winter months because differential heating is not as strong. Rather, the passage of winter storms has a more significant impact upon surface winds. As a result, the wind direction can become more evenly distributed.

TOWER INSTRUMENTATION

Since 1979, meteorological data have been collected at LLNL. MET ONE instruments and an LSI-11 logger were used until January 1985, when they were replaced with HANDAR equipment. The instruments were polled every second and 15-min averages were computed by the logger. Horizontal wind speed and direction, standard deviation of wind direction, and temperature were measured at 10 and 40 m. Relative humidity was measured at 10 m. Table 1 lists the instruments used and their specifications.

Table 1. Instruments used at the LLNL tower.

Parameter	Instrument	Threshold	Accuracy	Other
Wind Speed	Three-cup anemometer	0.5 m s^{-1}	$\pm 0.15 \text{ m s}^{-1}$ or $\pm 2\%$	-
Wind Direction (1979 - 1984)	MET-ONE Bivane	0.3 m s^{-1}	$\pm 3^\circ$	Distance constant 1.0 m
Wind Direction (1985 to present)	HANDAR Wind Vane	0.5 m s^{-1}	$\pm 3^\circ$	Distance constant 4.5 m
Temperature	Thermistors	-	$\pm 0.1^\circ\text{C}$	-
Relative Humidity	Thin-film capacitor	-	0-80% $\pm 2\%$ 80-100% $\pm 5\%$	Response time < 30 s to 90% change at 20°C

DATA ANALYSIS

INTRODUCTION

Fifteen-minute-interval data at the 10-m level of the LLNL tower were collected between January 1979 and December 1987. These data were checked for values out of range or times where all instruments did not report. The time periods when these problems occurred were small in number and were removed from the data set. The remaining 15-minute-interval data were summarized into hourly averages. Wind speed, temperature, and relative humidity were scalar averaged. Wind direction was weighted with the wind speed and polar averaged. The hourly value of sigma theta (σ_θ) was computed by the root-mean-square method. These hourly data were used to construct seasonal diurnal averages and frequency distributions. From analysis of monthly data (presented in tabular form in appendices), we grouped the data into four seasons. Summer was defined as the months showing the most sea-breeze influence (June, July, and August); winter, the months showing synoptic-scale influence (December, January and February); and spring (March, April, and May) and fall (September, October, and November), as the transition months. The standard deviation of the horizontal crosswind component, the Pasquill-Gifford (P-G) stability, and the absolute humidity were also calculated and analyzed seasonally. Appendices A through H present the data analyzed in this report.

DATA CAPTURE

Data are missing for 10 months of the nine-year data set. The missing months are February 1980; February 1982; June, August, and September 1983; November and December 1984; August 1985; July 1986; and May 1987. There are also other shorter periods of missing data. The percent of data recovered in each month from 1979 to 1987 is summarized in Table 2.

In addition, there were a few months (January through May) in 1986 when the 10-m temperature was not available. During these months the 40-m temperature was used.

Because collection of relative humidity data began in June 1986 and the comparatively few data in the relative humidity data set, data from December 1987 to March 1988 and November to December 1988 were added to the analysis during preparation of this report. The relative humidity data are missing for April to October 1988, as well as July 1986, and January, February, April, and May 1987.

RESULTS

Wind Speed, u

Figure 3 shows the frequency distribution of wind speed for spring, fall and annual, and Figure 4 shows summer, winter and annual. (From this point forward, the figures are presented at the end of the report to facilitate comparison.) Spring and summer distributions are shifted toward higher speeds because there are more moderate and high speeds ($>3 \text{ m s}^{-1}$) during spring and summer due to sea-breeze activity.

Wind speed frequency distributions typically fit a Weibull distribution. The cumulative probability function of the Weibull distribution is

$$p(V < V_x) = 1 - \exp [-(V_x/c)^k] , \quad (1)$$

where V is the wind speed, V_x is the maximum of each wind speed category, c is the scale factor, and k is the shape factor. Each distribution in Figures 3 and 4 was fit with a Weibull distribution following Justus et al. (1978). The resulting values of c and k are given on the figures themselves.

Figures 5 through 9 show the diurnal variation of wind speed for each season and the entire year. The 10th, 25th, 50th, 75th and 90th percentiles were used to give an idea of the shape of the distribution. Although the median value of the diurnal pattern over an extended period such as a season or year does not reflect the daily wind speed, it does shed light on the driving forces that determine wind speed when short-term, transient fluctuations are removed. The 10th, 25th, 75th, and 90th percentiles demonstrate the fluctuation of the median; this fluctuation is discussed next.

In the spring (Figure 5), the wind speed is low at night, begins to increase at sunrise, reaches a typical maximum of 4.4 m s^{-1} at 1600 PST, and then decreases more rapidly to its nighttime minimum of 1.2 m s^{-1} at 0500 PST. Summertime (Figure 6) behavior is similar, but the maximum and minimum speeds are slightly higher (10 to 20%) than those for spring. Specifically, a

maximum of 4.8 m s^{-1} was reached at 1600 PST and a minimum of 1.5 m s^{-1} was reached at 0300 PST. The values are higher in the summer due to an increase in sea-breeze activity. Values in the fall and winter (Figures 7 and 8, respectively) are much lower than those in the spring and summer. The fall wind speed maximum of 3.4 m s^{-1} is reached an hour earlier (1500 PST), and the minimum of 1.0 m s^{-1} is reached at midnight. The winter maximum of 3.3 m s^{-1} is reached at 1400 PST, two hours earlier than in spring or summer. The wind speed decreases to 1.1 m s^{-1} at 2000 PST and remains at this speed until sunrise. On an annual basis (Figure 9), the maximum of 3.8 m s^{-1} is reached at 1500 PST and the minimum of 1.2 m s^{-1} is reached at 0200 PST.

Figures 10 through 14 show the diurnal variation of the wind speed distribution for each season and the year as a whole. Figure 11 (summer) shows the maximum near 5 m s^{-1} at 1600 to 1700 PST. There are also fewer low wind speeds ($< 3 \text{ m s}^{-1}$) during the midday in summer than in the other seasons. The occurrence of nighttime near-calm speeds increases during the fall and winter (Figures 12 and 13, respectively).

Wind Direction

Figures 15 through 19 are wind roses for each season and the entire year. Each diagram shows the frequency of occurrence of four wind speed classes equal to the length of the corresponding bar for each wind direction category. Wind direction categories are 22.5° wide, centered on each of eight wind directions. The frequency of occurrence of calm winds (0 to 1 ms^{-1}) are equally divided among the wind direction categories, and the radius of the center circle reflects this amount.

With the exception of winter (Figure 18), all seasonal and annual analyses show a maximum occurrence of south to southwest winds. Winter winds show a secondary maximum from the south, but a primary maximum from the north to northeast due to the passage of winter storms. Summer winds (Figure 16) are almost always (75%) from the south or southwest, resulting from the sea breeze.

Standard Deviation of Wind Direction, σ_θ

The standard deviation of horizontal wind direction is related to the atmosphere's dispersive quality. The value of σ_θ can be used to determine P-G stability class for direct input to models as turbulence data (Brode, 1987). Figure 20 shows σ_θ for spring, fall, and annual cumulative frequency distributions, and Figure 21 shows summer, winter, and annual distributions. All distributions are lognormal. The equation of best fit for the annual distribution is given on each figure. Spring and winter modes are at 12.5° ; summer, fall, and annual distributions show modes at 15° .

Figures 22 through 26 present diurnal variation of σ_θ and are similar to Figures 3 through 7. Daytime median σ_θ values are higher in summer than spring, and summer is approximately the same as fall; nighttime winter values are slightly higher, and daytime values slightly lower, than fall median values. Median winter σ_θ values show very little diurnal trend compared to the other seasons.

Pasquill-Gifford Stability

The Pasquill-Gifford (P-G) stability class can be found using σ_0 , wind speed, and time of day in the Modified Sigma Theta (MST) method (Brode, 1987). This method is based on initial estimates of stability using σ_0 , and then this estimate is modified based on time of day and wind speed (Tables 3 and 4). The higher wind speeds force stability toward neutral. This results in daytime categories of A through DD (D-Day) and nighttime categories of DN (D-Night) through F.

Figure 27 shows the probability distribution of stability for spring, fall, and annual and Figure 28 shows summer, winter, and annual. The most probable stability is category D. The categories A, C, E, and F are fairly probable, while the intermediate category of B is less probable.

Table 5 gives a joint frequency distribution of wind speed and stability for the entire nine years of data. This table shows the effect wind speed has on stability. The higher wind speeds force stability toward neutral, while the lighter wind speeds allow extreme stabilities (A or F). The method of determining stability requires that there are no occurrences of categories A through DD during the night and no occurrences of DN through F during the day. Figures 29 through 33 show the diurnal variation of the stability probability distribution for the four seasons and annually. The occurrence of A stability is greater during the summer than the spring due to the increase in surface heating. During the fall and winter, F stability is greater than spring and summer values due to weaker nighttime flow patterns.

Figures 34 through 38 show wind roses for each stability class during each season and the entire year. Again, the predominance of south and southwest winds during the spring and summer is evident. Daytime winds in spring and summer are primarily from the southwest under unstable conditions and from the south under neutral conditions with higher wind speeds. Nighttime winds in spring and summer under neutral conditions are primarily from the south, while spring winds under stable conditions are from the south and east quadrants.

Daytime winds in fall under unstable conditions are primarily from the southwest with a significant percentage of northerly winds as stability becomes neutral. Under neutral conditions, day or night, and stable conditions, winds are primarily from the south.

During the winter, daytime unstable winds are mostly from the north. Southerly winds are a significant portion of the distribution when the stability is neutral. At night, however, under neutral conditions, southerly flow is dominant, becoming northeasterly as conditions become more stable. These nighttime stable winds are probably due to weak drainage from the Altamont Hills to the east of LLNL.

On an annual basis, daytime unstable winds are most likely to be southwesterly, while neutral and nighttime stable winds are primarily southerly.

Table 3. Lateral wind direction turbulence criteria for initial estimate of P-G Stability Category. Use with Table 4 (from Brode, 1987).

Initial estimate of Pasquill stability category	Standard deviation of horizontal wind direction fluctuations, σ_θ , in degrees
A	$22.5 < \sigma_\theta$
B	$17.5 \leq \sigma_\theta < 22.5$
C	$12.5 \leq \sigma_\theta < 17.5$
D	$7.5 \leq \sigma_\theta < 12.5$
E	$3.8 \leq \sigma_\theta < 7.5$
F	$\sigma_\theta < 3.8$

Table 4. Wind speed adjustments for determining final estimate of P-G Stability Category from σ_θ . Use with Table 3 (from Brode, 1987).

	Initial estimated category	10-m scalar wind speed (u) ($m s^{-1}$)	Final estimate of stability category
Daytime	A	$u < 3$	A
		$3 \leq u < 4$	B

Standard Deviation of Crosswind Wind Speed Component, σ_v

Another important parameter for turbulence and diffusion modeling is the standard deviation of the horizontal crosswind component, σ_v . It is defined as

$$\sigma_v = u \sigma_\theta , \quad (2)$$

where u is wind speed. Sigma v is a measure of the horizontal turbulence and has the effect of spreading a plume in the crosswind direction. For a given wind speed and height, σ_v is greater under unstable than stable conditions (Slade, 1968).

From statistical turbulence theory, σ_v is proportional to eddy diffusivity as follows:

$$K_m(y) = \sigma_v^2 \int_0^{t_0} R(\xi) d\xi , \quad (3)$$

where $R(\xi)$ is a time-varying correlation coefficient between eddy velocities at times t and $t+\xi$ (Sutton, 1953).

Figures 39 through 43 show diurnal trends in σ_y and are similar to Figures 5 through 9 and 22 through 26. The diurnal trends for all seasons show maxima at 1300 PST (usually unstable) and minima near midnight, with the exception of winter, which has a minimum at 2000 PST (usually stable). Diurnal variation is greatest in summer and least in winter because the diurnal variation of wind speed is greater in summer.

Mixing Height

Mixing height is defined as the height above the surface through which there is vigorous vertical mixing. Although mixing height was not measured at LLNL, it can be approximated from routine meteorological measurements that are performed at nearby National Weather Service stations. Holtzworth (1972) presents a compilation of these mixing-height calculations performed twice a day for each of the four seasons, and these calculations are presented as diagrams of the U.S. with mixing height isopleths. The data in Table 6 are interpolated from the diagrams in Holtzworth's study.

Mixing height is generally related to the P-G stability categories. Mixing height usually decreases with increasing stability. For dispersion modeling, the highest mixing height (1200 m) is assigned to stability class A and the lowest (440 m) to stability class F. The highest morning mixing height (700 m) and the lowest afternoon mixing height are assigned to the two neutral stabilities. The mixing height values for B, C, and E stabilities are interpolated from the A, D, and F stabilities. The mixing heights are presented in Table 7.

Temperature

Figures 44 through 48 show the diurnal average variation of temperature at 10 m for each season and on an annual basis. Each figure shows the mean value at 10 m, standard deviation, maximum, and minimum for each hour.

Mean daily maximum and minimum hourly averaged temperatures for all seasons and the year as a whole from Figures 44 through 48 are given in Table 8.

Relative Humidity

Figures 49 through 53 show the average diurnal variation of relative humidity for each season and the entire year. Each figure shows the mean, standard deviation, maximum, and minimum values for each hour.

The diurnal variation has the general shape of an inverted temperature curve, with the maximum occurring at night with cooler temperatures and the minimum occurring during the day with warmer temperatures. This is due to the way relative humidity is defined. It is the ratio of the amount of water vapor in the air to the amount the air could potentially hold without formation of condensation. Because warm air can hold more moisture than cold air, minimum relative humidity values would be expected to correspond to warmer daytime temperatures, and maximum relative humidity values would be expected to occur during the night.

Table 6. Mixing height (m) at Livermore, CA from Holtzworth (1972).

	Annual	Winter	Spring	Summer	Autumn
Morning	490	470	700	450	440
Afternoon	1000	750	1200	800	950

Table 7. Mixing height (m) for each P-G stability category at Livermore, CA.

	A	B	C	DD	DN	E	F
Mixing height (m)	1200	1050	900	750	700	570	440

Table 8. Maximum and minimum mean temperatures for LLNL tower data set (1979 to 1987).

Season	Minimum °C	Time (PST)	Maximum °C	Time (PST)
Spring	8.1	0500	18.6	1400
Summer	12.9	0400	27.7	1400
Fall	10.7	0500	21.8	1400
Winter	5.7	0600	12.7	1400
Annual	9.4	0500	20.2	1400

Daytime minimums correspond closely to the time of maximum temperature. Nighttime maximums occur shortly before the time of sunrise. Table 9 gives mean daily maximum and minimum hour-averaged relative humidity and time of occurrence for each season and annually.

Absolute Humidity

Because atmospheric moisture content is a conservative property, i.e., remains fairly constant with time, relative humidity is not the best way to quantify this parameter. A better estimate of atmospheric moisture is absolute humidity, ρ_v . Absolute humidity can be calculated from relative humidity and temperature:

$$\rho_v = \frac{R}{100} \frac{e_{s0}}{R_v T} \exp \left[\frac{L_v}{R_v} \left(\frac{1}{T_0} - \frac{1}{T} \right) \right] , \quad (4)$$

where e_{s0} is saturation vapor pressure at standard temperature and pressure and is equal to 6.11 mb, R_v is the specific gas constant for water vapor and is equal to $0.4615 \text{ Jg}^{-1}\text{K}^{-1}$, T_0 is standard temperature (273.16 K), T is temperature in Kelvin, and L_v is latent heat of vaporization of water at temperature, T , and has the functional form

$$L_v = 2501 \text{ Jg}^{-1} - 2.266 \text{ Jg}^{-1}\text{K}^{-1} (T - 273.16) . \quad (5)$$

Equation (4) simplifies to

$$\rho_v = \frac{R}{100} \frac{1324}{T} \exp \left[(6759 - 4.910 T) \left(\frac{1}{T_0} - \frac{1}{T} \right) \right] . \quad (6)$$

Table 9. Mean maximum and minimum relative humidity for LLNL tower data set (1979 to 1987).

Season	Minimum %	Time (PST)	Maximum %	Time (PST)
Spring	51.9	1500	88.1	0500
Summer	41.6	1500	92.6	0500
Fall	50.3	1400	84.2	0600
Winter	61.3	1500	80.5	0700
Annual	51.3	1400	85.4	0500

Table 10 gives absolute humidity in $\text{g} \cdot \text{m}^{-3}$ for a range of relative humidities (0 to 100%) and temperatures (0 to 42°C).

Figure 54 shows the probability distribution of absolute humidity for spring, fall, and annual time periods, and Figure 55 shows the distributions for summer, winter, and annual time periods. Table 11 gives modal values for each season and annually.

Figures 56 through 60 show the average diurnal variation of the mean, the standard deviation, and the maximum and minimum absolute humidity for each season and the entire year. All figures show the expected lack of variability in atmospheric moisture. Table 11 gives mean values for each season and annually. Summer values are higher than winter because the summer sea breezes bring moist ocean air to Livermore.

FREQUENCY OF FAVORABLE METEOROLOGICAL CONDITIONS

Because wind and stability data for nine years are available, we can use this database to determine the frequency of any combination of meteorological conditions. Engineering and health-safety parameters can be studied to create a set of meteorological criteria that could cause a hazard if a release of a hazardous material should occur. A program can then be written to comb the database to count the number of times this specific set of conditions was found.

As a test of the methodology, undesirable meteorological conditions were selected on the basis of previous experience with atmospheric dispersion. The undesirable conditions are as follows:

- (1) Extremely unstable conditions (A Stability) -- Vertical looping of the plume may occur causing high concentrations of effluent to impact the ground for short durations very close to the release point.
- (2) Extremely stable conditions (F Stability) -- The lack of vertical and horizontal mixing leads to high concentrations farther downwind. With an elevated source, this high concentration may not reach the surface until the plume impacts a hill.
- (3) Very low winds (Winds less than 1 m s^{-1}) -- "Calms" can cause high concentrations under any stability category. Since the MST method of stability-class determination requires that A and F stabilities occur only during times of low wind speed, this criterion was the overriding factor in the analysis.

We were interested in the frequency of 4-h periods without these conditions and developed an algorithm that kept account of the beginning time of each 4-h period. The program was repeated for the summer and winter months. Spring and fall months were grouped together and presented as the transition months.

Table 11. Absolute humidity ($\text{g}\cdot\text{m}^{-3}$) statistics for LLNL tower data set (1979 to 1987).

Season	Mean	Mode	Number of Months
Spring	7.6	8.0	2
Summer	10.7	11.5	5
Fall	9.2	11.2	7
Winter	6.5	4.9	5
Annual	8.7	11.5	19

The results of this database search are presented as Figure 61. The only time where the probability of desirable periods exceeds 50 percent is for the summer afternoons. This may be due to the persistence of strong sea-breezes during these times. The lowest probability of desirable meteorological periods occurs during the winter months, especially during the night; this is caused by reduced winds.

STAR FORMAT

Because these data may be used for modeling environmental effects and because many of U.S. Environmental Protection Agency's long-term models require meteorological data in the STAR format used by the National Climatic Data Center (Doty, 1983), the data are summarized in the STAR format (Appendix I). The STAR format is the three-dimensional, joint frequency of occurrence of wind direction, P-G stability, and wind speed. Sixteen classes of wind direction are used and each is coded as wind coming from the labeled direction. Six stability classes (A through F) are used and wind speed is divided into six classes also.

COMPARISON TO ANOTHER ON-SITE LOCATION

To investigate the applicability of the above climatological data to other locations of the laboratory, data for the months of February and March 1988 from the instruments on an exhaust stack at Building 222 at LLNL (B-222) were compared to the LLNL tower data. Measured and calculated parameters used for the comparison were horizontal wind speed and direction, σ_θ , stability, σ_V , and temperature.

Instruments on the exhaust stack of B-222 are the same as those on the LLNL tower. Five-minute average horizontal wind speed, wind direction, standard deviation of wind direction, and 15-min average temperature data were

•

stored in a separate HANDAR 540A logger. Instruments are approximately 30 m above the ground. Instrument ranges and accuracies are the same as for LLNL tower instruments. Fifteen-minute averages were calculated from the 5-min-average recorded data from B-222 are compared with 15-min-average LLNL tower data.

RESULTS

Wind Speed

Wind speeds at B-222 and the LLNL tower are quite similar. Figure 62 shows the distribution of the difference in wind speed from the two locations. The difference in speed at the two locations is $\pm 0.125 \text{ m s}^{-1}$ about 16% of the time and is within $\pm 1 \text{ m s}^{-1}$ 80% of the time. The LLNL 40 m wind speeds are slightly greater than B-222 30-m level, and the LLNL 10 m wind speeds are slightly less and B-222 30-m winds.

The effect of surface roughness is illustrated in Tables 12 and 13. These tables present joint frequency distributions of the 30-m B-222 wind speed and the 10- and 40-m LLNL tower wind speeds, respectively. Table 12 shows B-222 speeds having a nearly one-to-one correspondence with the 10-m LLNL tower wind speed. However, Table 13 shows a slight shift in the distribution toward the 40-m LLNL tower wind speed at speeds greater than 3 m s^{-1} . One would expect the 30-m B-222 speeds to be more closely related to the 40-m LLNL tower speeds than those of 10-m. This is not the case due to the greater surface roughness in the vicinity of B-222 caused by surrounding buildings.

Wind Direction

Wind direction at the 30-m level of B-222 is quite similar to both the 10- and 40-m wind direction at the LLNL tower (Figure 63). This analysis is based on wind direction only when the wind speed was greater than 1 m s^{-1} to eliminate the uncertainty in wind direction with low wind speeds. Wind direction at B-222 is within $\pm 20^\circ$ of the 10-m wind direction at the LLNL tower 69% of the time and the 40-m wind direction 72% of the time. One would not expect much higher agreement between the two locations due to the interference of the buildings near B-222. The small increase in the distribution at -120° and $+120^\circ$ often occurs when the wind at the LLNL tower is northerly. The wind at B-222 oscillates between SE and SW. No explanation can be offered for this phenomenon.

Stability, σ_v , and σ_θ

Stability compares very well at the two locations. Over 45% of the time, the P-G class is the same, and over 80% of the time, it is within one category (Figure 64).

The B-222 σ_v values are very close to LLNL-tower σ_v values. Nearly 40% are within $\pm 0.125 \text{ ms}^{-1}$ of each other, and almost 75% are within $\pm 0.375 \text{ ms}^{-1}$ (Figure 65).

The σ_θ values for the two locations were not directly compared because raw σ_θ values are not as physically meaningful as stability and σ_y , which are derived from it.

Temperature

Under cloudless skies, temperature decreases with height during the day and increases with height at night. Therefore, one would expect a 30-m temperature would be closer to a 40-m temperature than to a 10-m temperature. This is illustrated in Figure 66. The distribution of the difference between the 40-m LLNL and 30-m B-222 temperatures is narrower than the similar distribution using the 10-m LLNL temperature. The temperature at B-222 is within $\pm 1^\circ\text{C}$ of the 10-m LLNL temperature over 65% of the time and the 40-m LLNL temperature over 85% of the time.

CONCLUSIONS

Overall, the 30-m data at B-222 is very similar to both the 10- and 40-m LLNL tower data. This study shows raw LLNL 15-min-average data are applicable to another site at the laboratory. This being the case, the derived climatology can also be used for other on-site locations. However, the slight differences in wind speed, for example, point out that local adjustments should be made when using the data at other locations. Local effects such as differences in surface roughness of the upwind fetch may need to be considered.

FUTURE STUDY OF THE LLNL METEOROLOGICAL DATABASE

This study describes a database that can be a resource for future research of meteorology of the Livermore Valley and the San Francisco Bay Area.

More specifically, the 40-m level of the LLNL tower can be analyzed with the 10-m data to produce vertical profiles of wind speed, wind direction, horizontal turbulence, and temperature.

Algorithms can be developed to investigate the persistence of wind direction. Persistence is the probability of the current wind continuing in the same direction for some time in the future.

A method currently exists to compute mixing height using balloon-sounding data from a National Weather Service (NWS) station. However, the nearest NWS is in Oakland, about 40 miles away, and may not accurately represent the depth of the mixing layer at LLNL. An acoustic sounder could be installed at LLNL to measure the height of the mixing layer. Additional measurements available from a sounder include vertical profiles of wind from the surface to about one kilometer.

Meteorological data may be obtained from nearby sites for comparison with the LLNL data set. Nearby locations of meteorological data collection include Site 300 (near Tracy), Livermore Airport, Altamont Pass, and Bay Area Air Quality Management District's station in Livermore. A comprehensive set of wind flow data for the area may assist researchers in constructing models of wind fields in complex terrain.

ACKNOWLEDGMENTS

The authors wish to thank Joe Shinn for his support and editorial review; Ron Baskett and Harry Galles for editorial review; Cleo O. Fry for field and technical support for B-222 instrumentation; Stan Martins for technical support in data-collection software at B-222; Mike Novo for cartographic assistance; Dave Brekke, Pat Ellis, and Jon Welch for their assistance in transferring the LLNL tower data to the PC computer equipment; and Wendy Lucido and Sherry Kenmille for word processing. Work performed under the auspices of the U.S. Department of Energy by the Lawrence Livermore National Laboratory under Contract W-7405-Eng-48.

SUMMARY OF FIGURES

Figures 3 and 4 show the cumulative frequency of occurrence of the wind speed (10-m height) for each season and annually. Refer to these diagrams to find the probability of wind below a certain wind speed. These diagrams show that the winter and fall have a higher frequency of lighter winds than the summer and spring. Expressions for the best fit to the Weibull distribution (Eq.1) are provided.

Figures 5 through 9 show the seasonal and annual cumulative frequency of occurrence of wind speed for each hour of the day. For instance, 50 percent of the wind speeds fall below the solid line.

Figures 10 through 14 show the seasonal and annual lines of constant frequency of occurrence of the wind speed (10-m height) for each hour of the day. Lines of constant frequency are drawn and illustrate the daily patterns of frequency density.

Figures 3 through 14 demonstrate the high frequency of strong winds during the summer months, especially in the afternoon. This is due to the sea-breeze activity in the area. Heat produced in the interior valleys causes low pressure which draws cooler air from the sea. During the summer, this pressure gradient effect is very persistent on a daily cycle. During the winter, cooler inland temperatures and winter storms limit the number of days with sea-breeze winds.

Figures 15 through 19 are seasonal and annual wind roses. The length of a direction radius is related to frequency of wind from that direction. The frequency of wind speed classes are included for each wind direction.

Figures 20 through 26 show the seasonal and annual cumulative and hourly frequency of occurrence of σ_θ (10-m height). Sigma theta is the standard deviation of the wind angle. The wind vane is polled every second and the standard deviation of these readings is σ_θ . Sigma theta is a measure of the crosswind turbulence of the atmosphere.

Figures 27 and 28 show the seasonal and annual frequency of occurrence of the atmospheric stability categories generally used by EPA. This is often referred to as Pasquill-Gifford stability or P-G class. Atmospheric stability is related to dispersion of airborne particles. Plumes or puffs spread more readily under A stability (very unstable) than F stability (very stable). Neutral stability (P-G class D) is divided into daytime and nighttime classes for specific uses.

Figures 29 through 33 show the seasonal and annual frequency density of P-G class for each hour of the day. Unstable classes (A, B, and C) do not occur during the night and stable classes (E and F) do not appear during the day. The distribution of the stable classes does not change throughout the night. In the daytime, there is a high frequency of unstable classes before noon. In the afternoon, there is a higher frequency of neutral classes due to the higher wind speeds.

Figures 34 through 38 are the seasonal and annual wind roses associated with each stability category.

Figures 39 through 43 show the seasonal and annual cumulative frequency of occurrence of σ_v for each hour of the day. Sigma v is a measure of the horizontal spread of a plume. These figures indicate that a plume will spread faster during mid-day than at night.

Figures 44 through 48 show the seasonal and annual average and range of temperatures (10-m height) found in the nine-year data set. For each hour of the day, the solid line is the average temperature, 68% of temperatures occur within the bars, and the dotted lines indicate the extreme temperatures.

Figures 49 through 53 show the seasonal and annual average and range of relative humidity (10-m height). The relative humidity instrument was installed in 1986. By comparing Figures 48 and 53, you can see that the average relative humidity curve is the inverse of the temperature curve. This is because the amount of atmospheric water does not change with a daily pattern.

Figures 54 and 55 are seasonal and annual histograms of absolute humidity, which is a true measure of atmospheric water density. These figures show the obvious seasonal change in the absolute humidity. Summer air contains about three times the amount of water of winter air. Winter storms bring cold air from the north and warm, moist air from the south to give us precipitation despite the reduced water content of the air.

Figures 56 through 60 show that for each season there is no consistent daily pattern in the absolute humidity. Changes in water content occur with large-scale synoptic changes, which do not follow daily cycles.

Figure 61 shows the percent of time when the next four consecutive hours will have favorable conditions for dispersion. The criterion for this study were taken from experience with dispersion models. It is presented to illustrate a type of analysis that may be performed for a specific scenario.

Figures 62 through 66 show the difference in meteorological conditions as measured at Building 222 and on the two levels of the LLNL tower. The two sites are about 3/4 mile apart. Wind speeds at both sites are usually within 1 ms^{-1} . Wind directions are usually within 20° , excluding times of calm winds. Stability classes are the same over 45% of the time and within one class over 80% of the time. There are also small differences between the two sites in crosswind turbulence (σ_v) and temperature.

Spring

Wind Speed (m/s)

11-3	31-6	51-7	>7
------	------	------	----

Spring

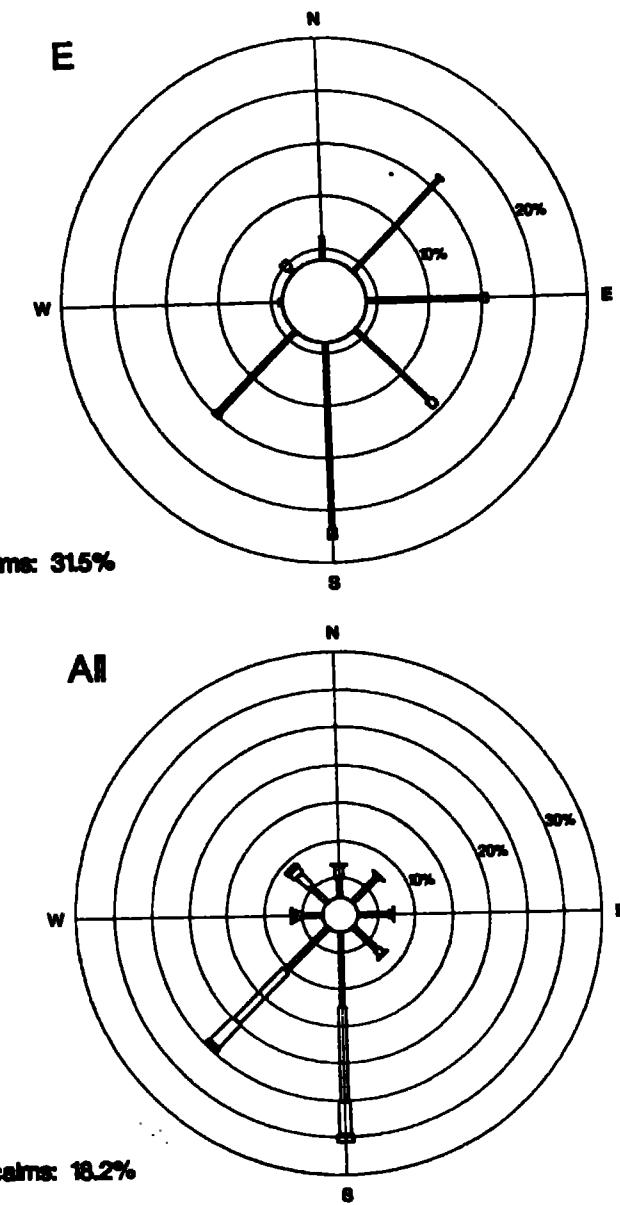

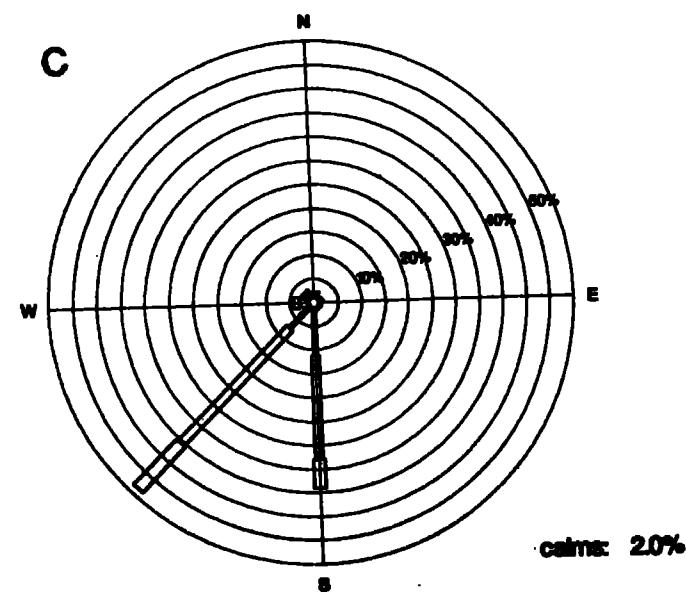

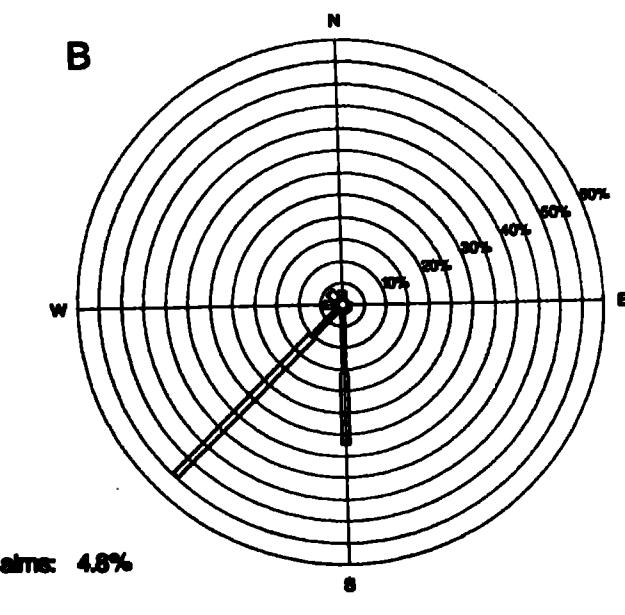

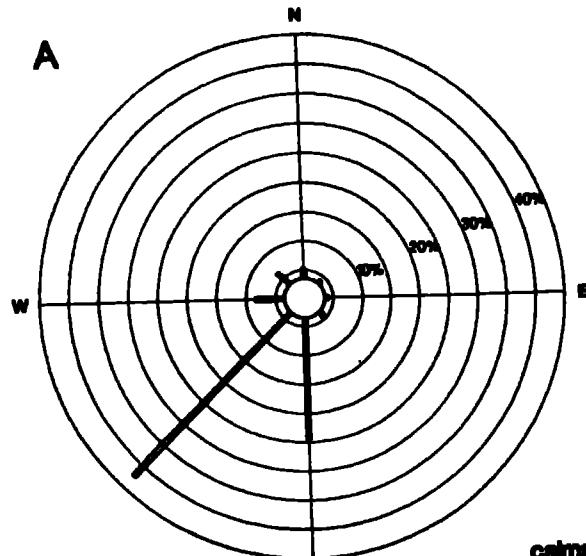

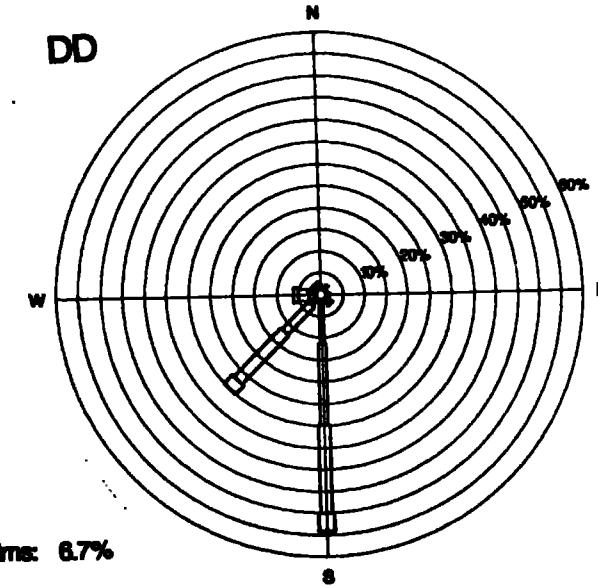

Figure 34. Wind rose for each stability during the springs of 1979 to 1987 at the LLNL tower.

Summer

Wind Speed (m/s)

A horizontal scale bar with tick marks at 11-3, 21-5, 31-7, and >7 m/s.

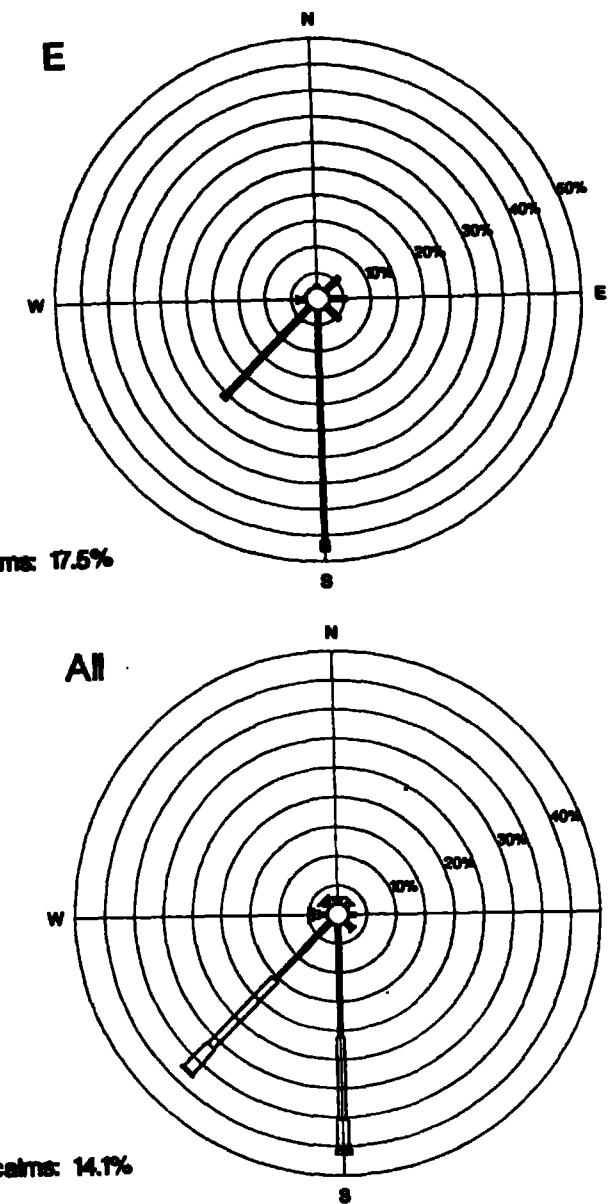

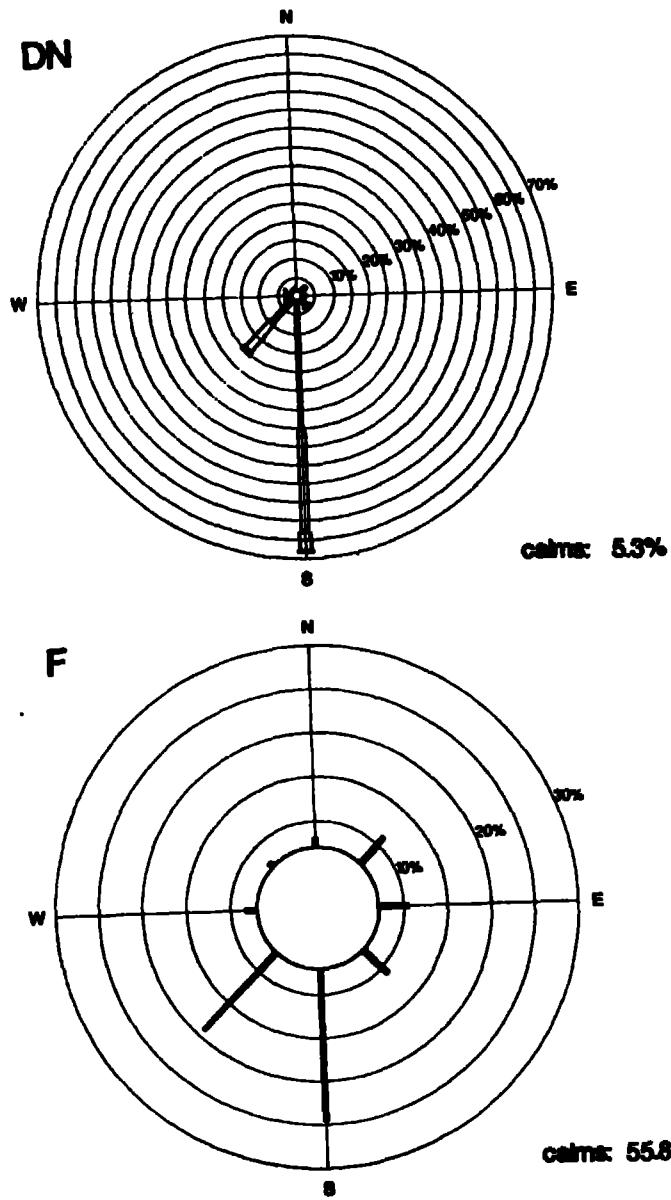

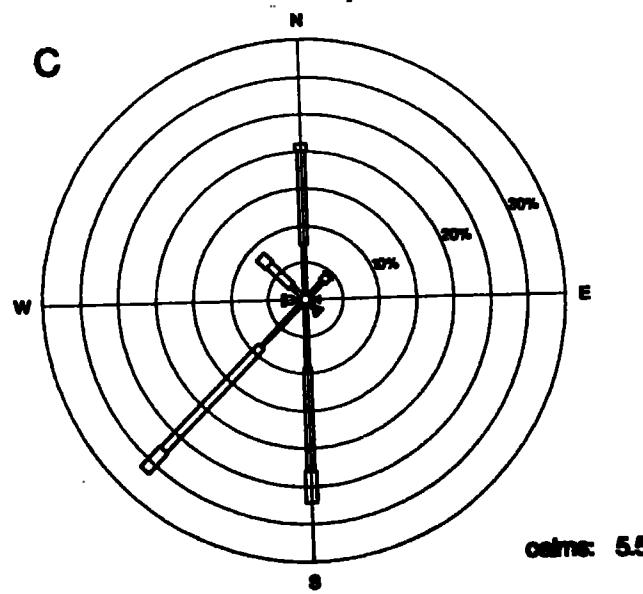

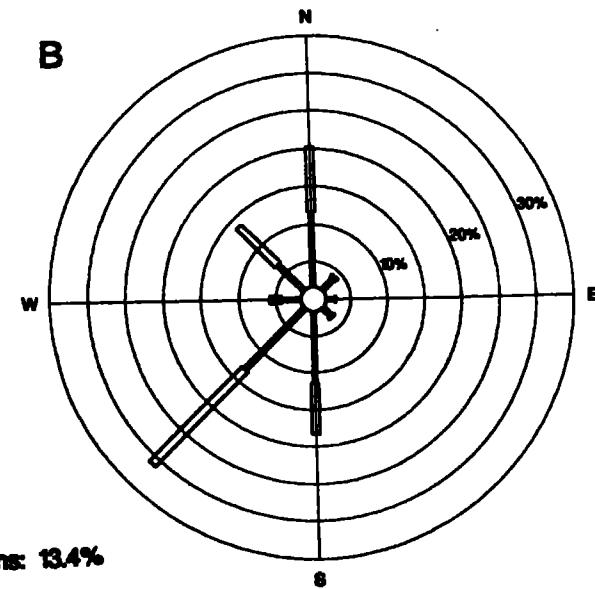

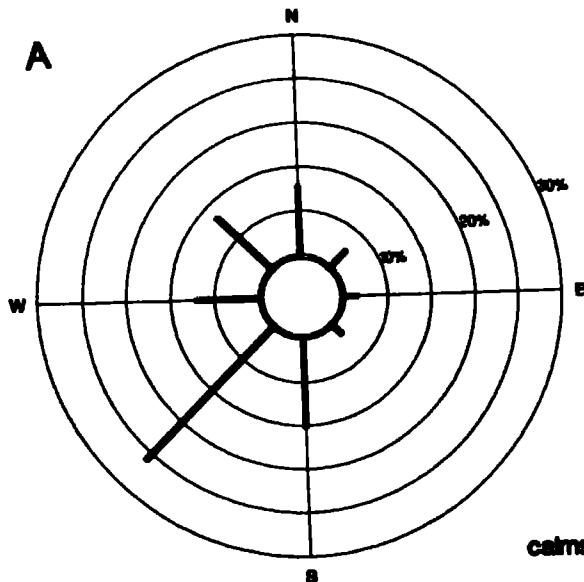

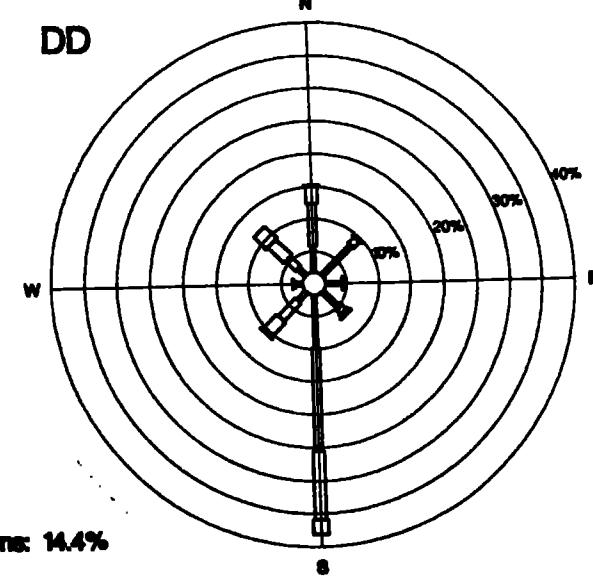

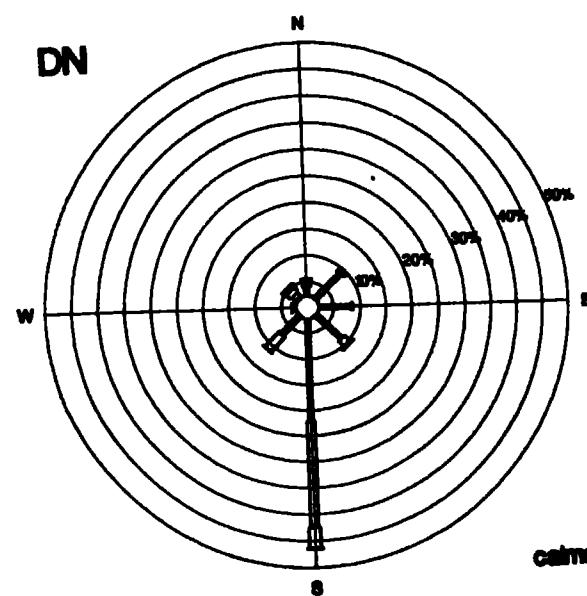

Figure 35. Wind rose for each stability during the summers of 1979 to 1987 at the LLNL tower.

Fall

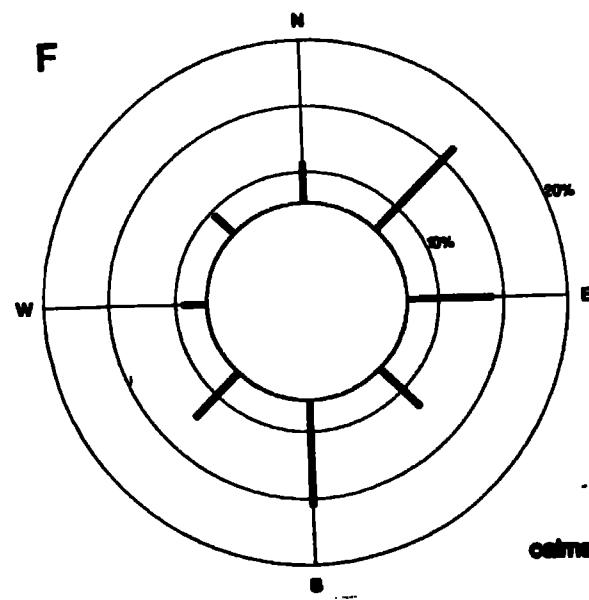

Wind Speed (m/s)

Fall

Wind Speed (m/s)

11-9	8.1-6	6.1-7	>7
------	-------	-------	----

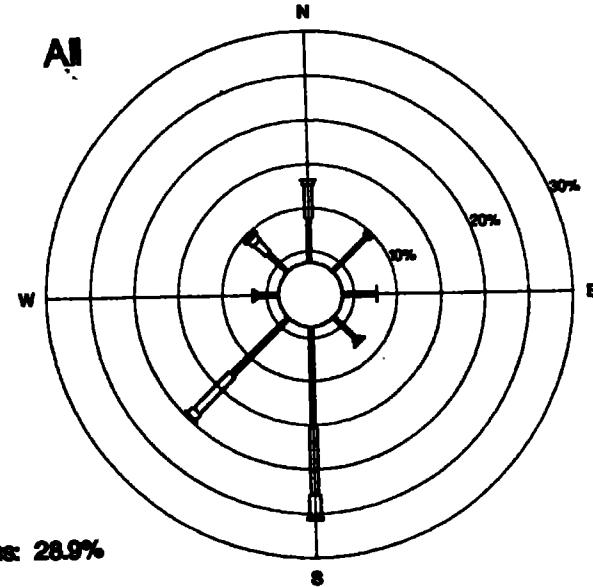

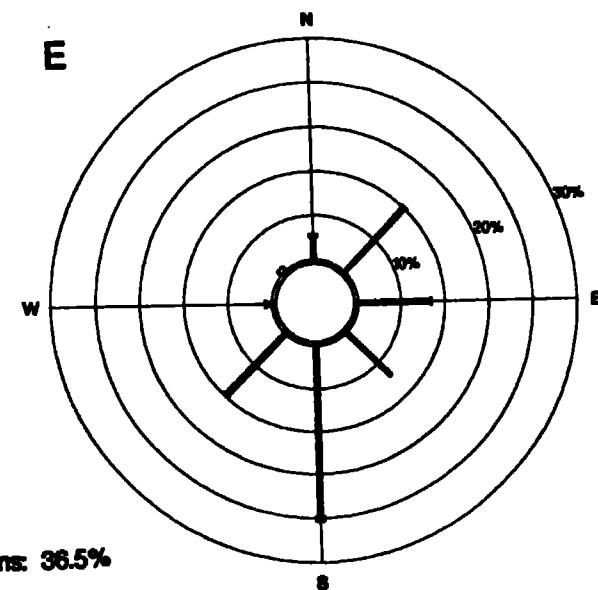

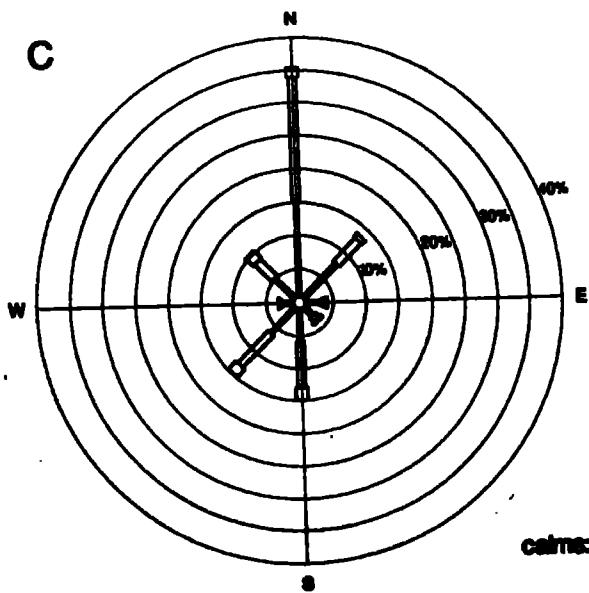

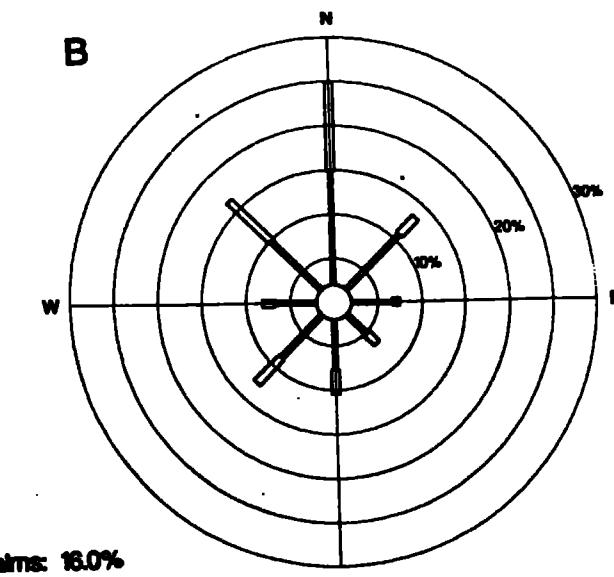

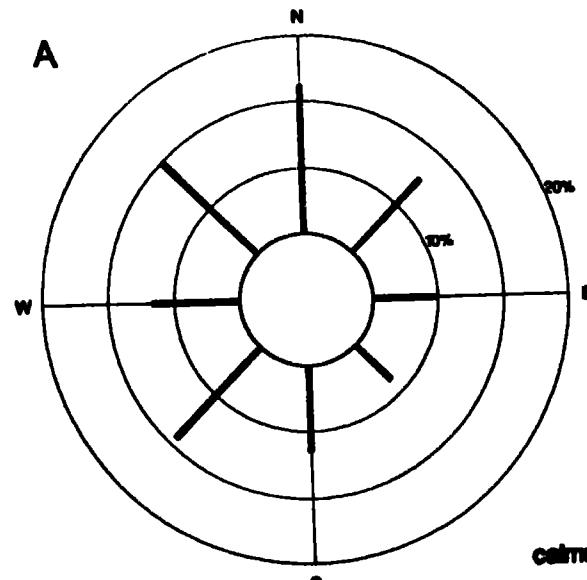

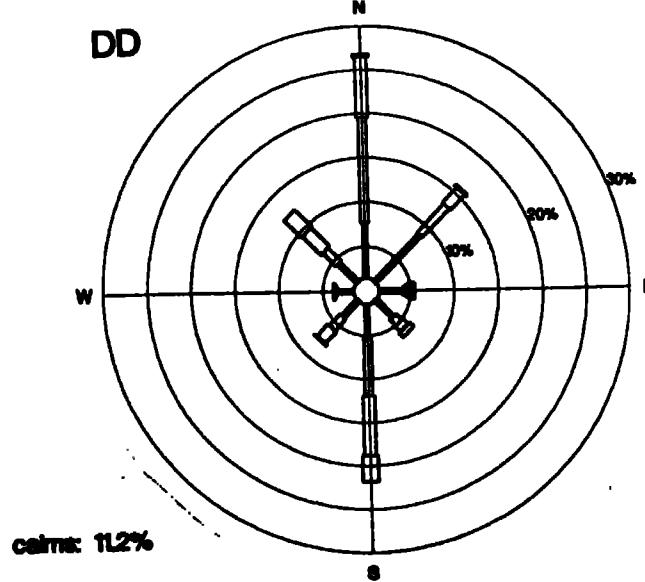

Figure 36. Wind rose for each stability during the falls of 1979 to 1987 at the LLNL tower.

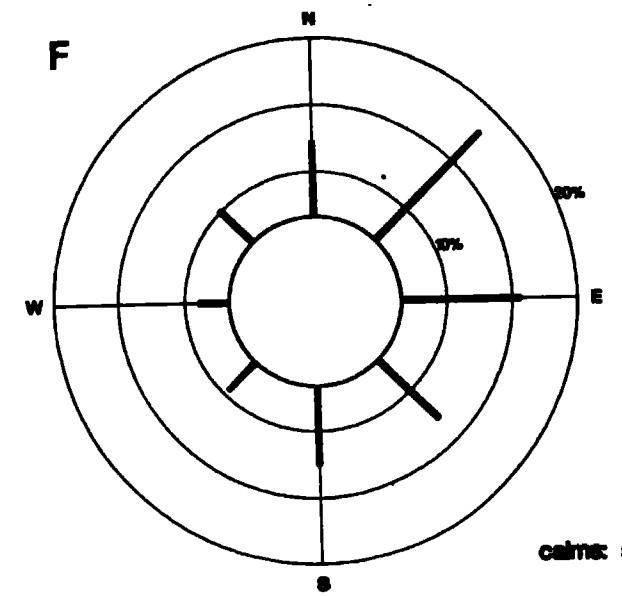

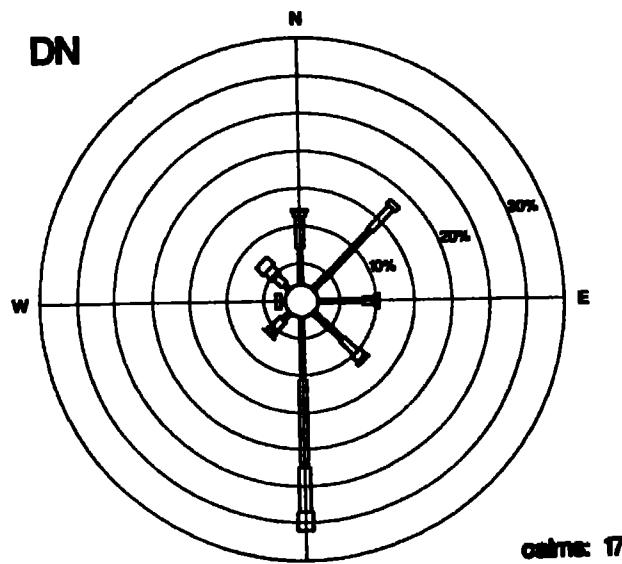

Winter

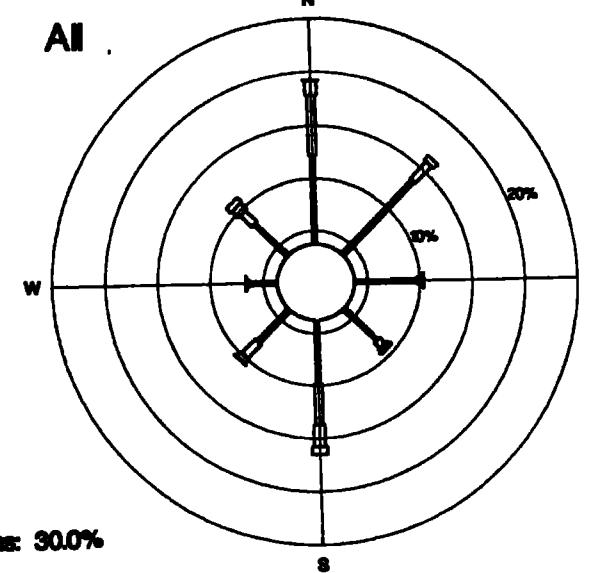

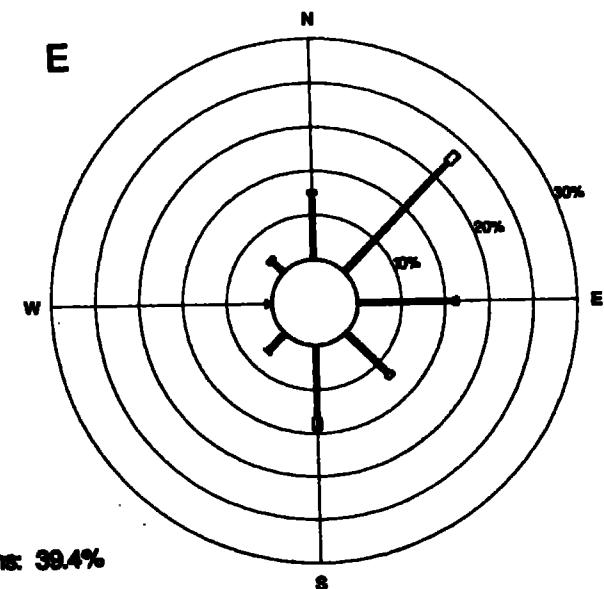

Wind Speed (m/s)

A horizontal scale bar with four segments. The first segment is labeled "11-8". The second segment is labeled "21-8". The third segment is labeled "31-7". The fourth segment is labeled ">7".

Winter

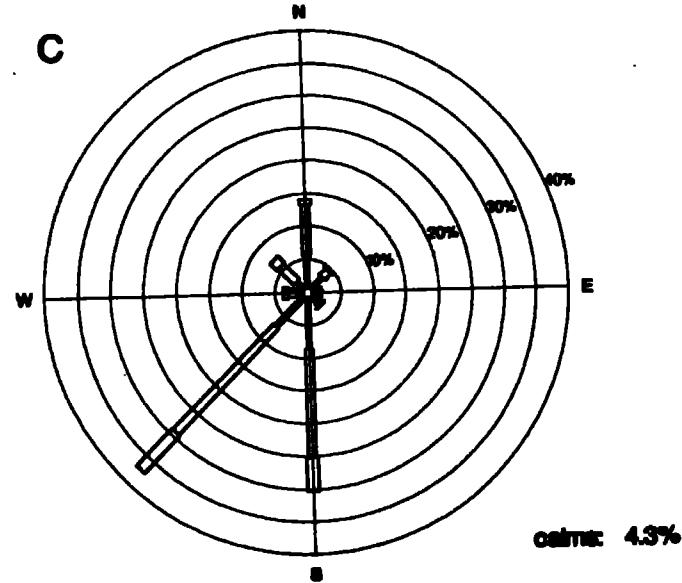

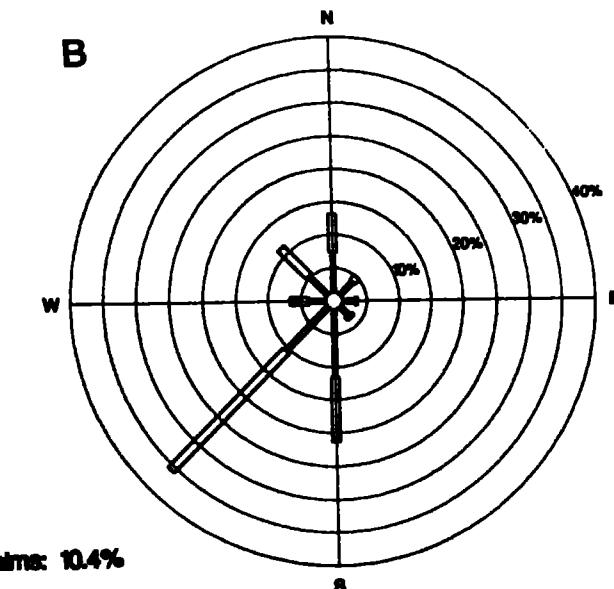

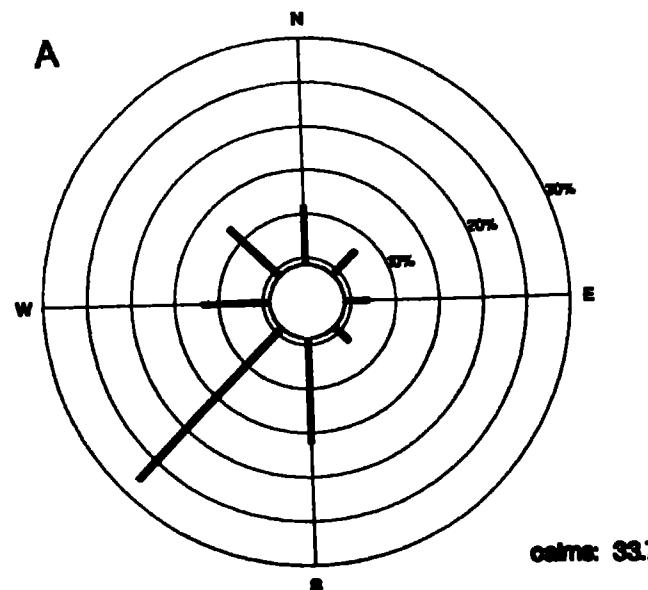

Wind Speed (m/s)

A horizontal scale bar for wind speed in m/s. It has four segments labeled 11-8, 8.1-6, 6.1-7, and >7, corresponding to increasing wind speeds.

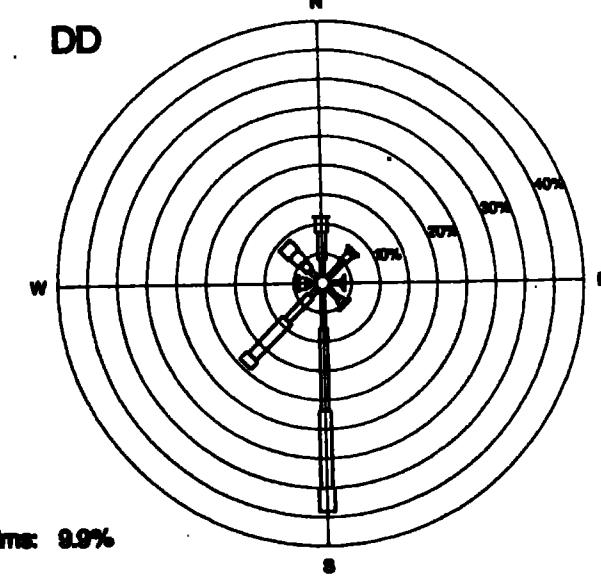

Figure 37. Wind rose for each stability during the winters of 1979 to 1987 at the LLNL tower.

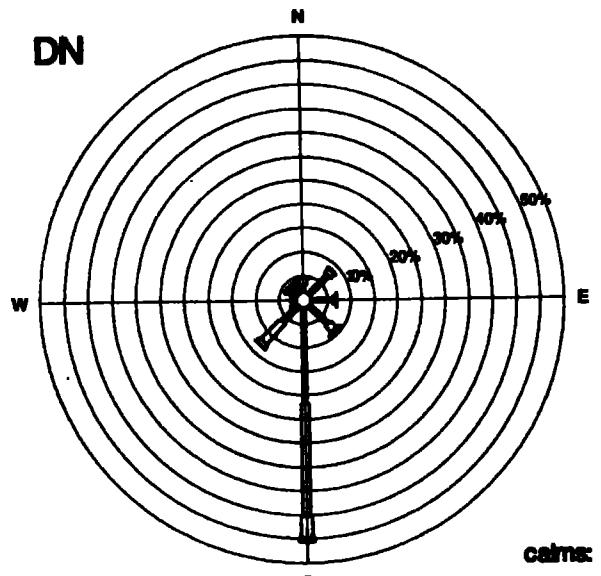

Annual

Wind Speed (m/s)

A horizontal scale bar with arrows pointing right. Below the arrows are numerical values: 11-3, 31-6, 61-7, and >7.

Annual

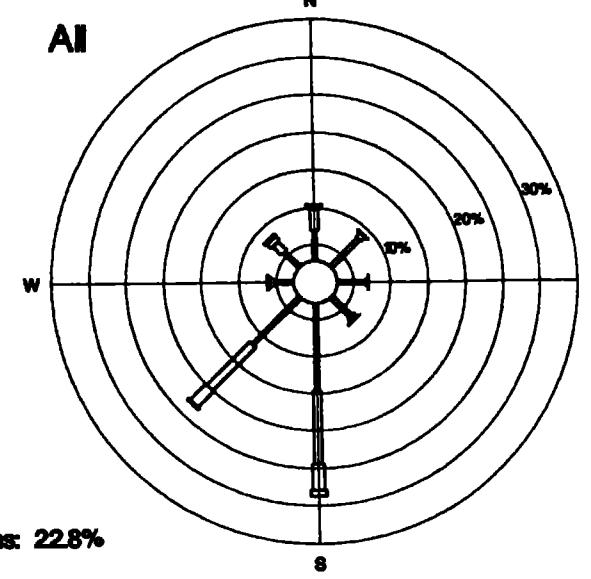

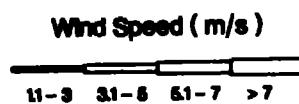

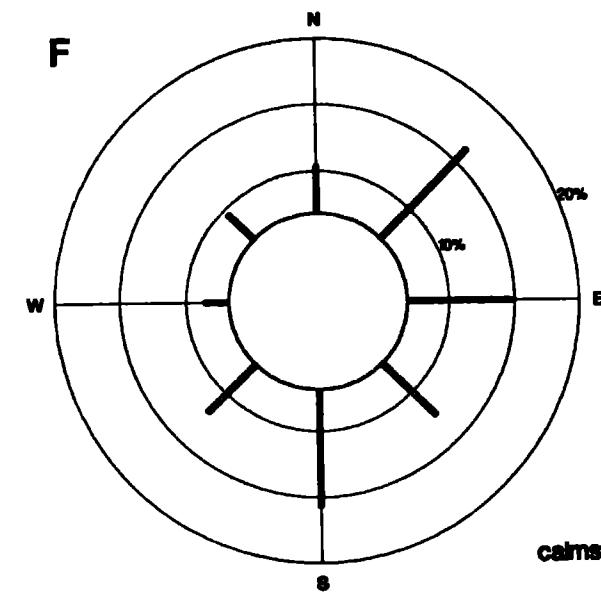

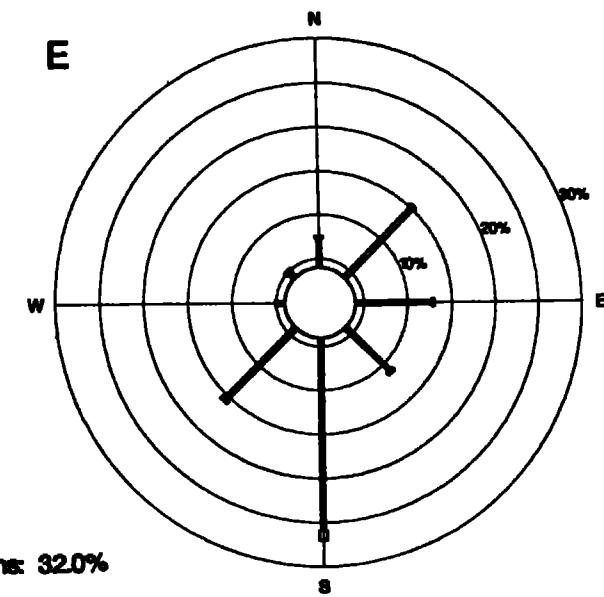

Figure 38. Wind rose for each stability during the years of 1979 to 1987 at the LLNL tower.

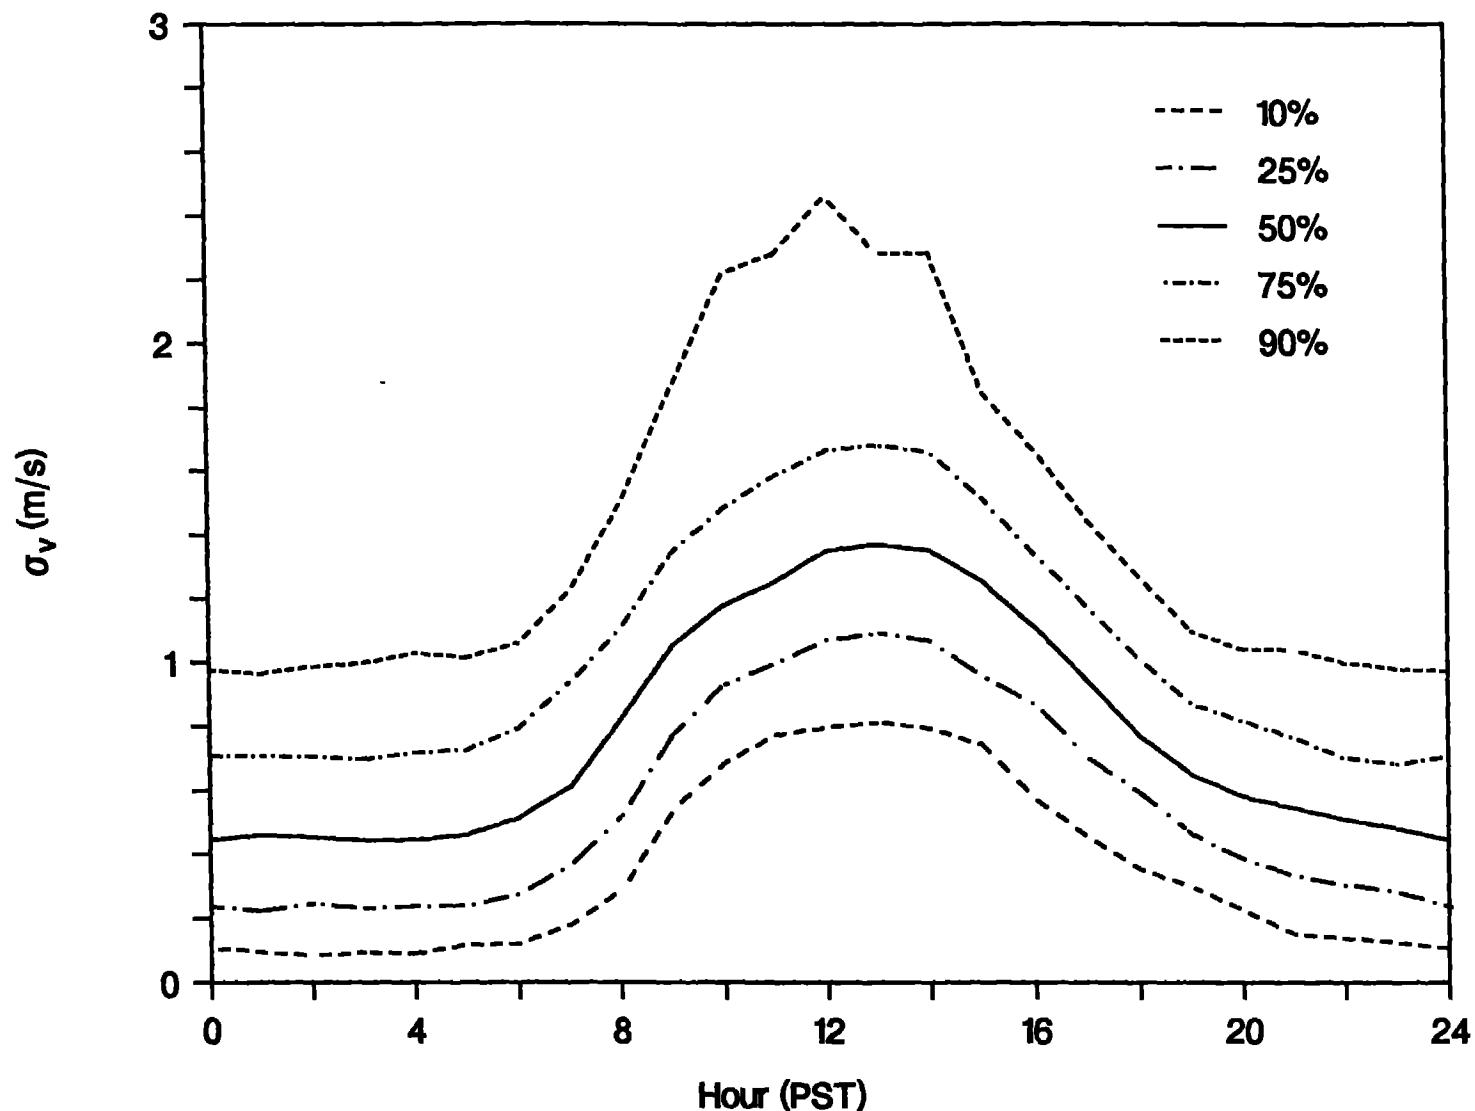

Figure 39. Diurnal variation of 10th, 25th, 50th, 75th, and 90th percentiles of σ_v during the springs of 1979 to 1987 at the LLNL tower.
